**Abstract:** Cancer survivors are at risk of decreasing health and psychosocial problems. Physical activity can reduce the risk of recurrence, death, and negative effects of cancer treatment. Several studies have investigated how the use of internet technology can increase the physical activity of survivors of cancer. The purpose of this review is to explore and identify the types of internet-based supportive education interventions to increase the physical activity of cancer survivors. We followed the methodology for scoping studies which consists of identifying the research question, locating relevant studies, selecting studies, charting the data, and collating, summarizing, and reporting the results. The search method used several electronic databases namely Google Scholar, Proquest, PubMed, and Scopus. Articles obtained from keywords: internet-based; supportive education; physical activity; cancer survivors. The inclusion criteria are: peer reviewed articles, publication year from 2008 to 2018 and has a minimal research design quasi experiment. Out of 5375 original articles identified in the literature search, 15 articles were analysed. Online support groups are the most frequently studied method of educational intervention, followed by interactive messages and web forums. Most studies showed improved results on intensity of physical activity. Online groups can improve the wellbeing of survivors of cancer by providing opportunities to engage in social networking, connect with others with similar cancer experiences, and obtain cancer related information. Based on the findings of this review. Supportive education through internet technology approaches can encourage increased physical activity and changes in health behavior of survivors of cancer. Future research should consider the potential role of social media in addressing the unmet needs of survivors of cancer and in particular the implications for clinical and public health practice.

**Keywords:** Internet-based; supportive education; physical activity; cancer survivors

1. **Introduction**

Cancer is the second leading cause of death in the world, and it’s responsible for 8.8 million deaths by 2015. Globally, nearly 1 in 6 deaths are caused by cancer. It’s indicates that cancer is one of the six most deadly diseases that affect the mortality rate of the world. The most common cause of death from cancer is lung cancer that is 1.69 million deaths (Stewart & Wild, 2014).
Advances in early diagnosis and treatment of cancer have an impact on increasing survival of cancer survivors. While survivors of cancer who have successfully completed their primary treatment hope to be able to return to work or back to life before being diagnosed with cancer.

Cancer survivors are at risk of decreased health and psychosocial problems. Cancer treatment can lead to increased fatigue, decreased physical activity, and decreased quality of life (Fong et al., 2012). Long term negative consequences of cancer and treatment related side-effects are common and often debilitating. Pain problem, sleep problems, physical side effects (e.g. lymphoedema), weight gain, anxiety and depression, fear of cancer recurrence and impaired quality of life (QoL) are all commonly reported (Roberts et al., 2017).

Physical activity is an intervention that potentially relieves cancer-related residual symptoms and helps patients return to the health status before treatment. Physical activity participation has been associated with reduced cancer-specific and all-cause mortality in breast and colorectal cancer survivors. Furthermore, PA participation is associated with better quality of life and psychological health of cancer survivors (Park et al., 2016).

Several training programs have been developed and tested to encourage cancer survivors to participate in physical activity including education and counseling. Several studies have shown that recommendations from oncologists, exercise suggestions, and sports education have managed to motivate patients to increase the amount of their physical activity especially when combined with telephone or community support (Patrick, Pratt, & Sallis, 2009). Furthermore, Vallance et al. also reported that giving physical print media and pedometer is an effective tool to increase the level of physical activity among survivors of breast cancer (Vallance J K, et al, 2007).

The development and widespread use of internet technology, smartphones and mobile technology has driven the intervention of changes in digital health behavior. Ofcom Communications Market report for the UK has shown that the proportion of adults going online using a mobile phone has risen from 20% in 2009 to 66% in 2016 and 71% of adults own a smartphone (Ofcom, 2017). Use of internet technology such as email, mobile apps, video conferences (e.g. Skype), social media, websites and online patient portals that improve access to information, connecting patients with health care and as approach to remote behavior change interventions (Roberts et al., 2017).

Among internet applications is an effort to promote the participation of physical activity and dietary behavior such as research by Mateo et al in 2015. The results show that cell phone-based interventions are associated with weight loss and improvement physical activity showed significant improvement. Mobile-based application interventions can be a useful tool for improving physical activity and dietary interventions (Mateo et al., 2015). The aim of this review is to explore and identify the types of internet-based supportive education interventions to increase the physical activity of cancer survivors.

2. Methods

We followed the methodology for scoping studies which consists of identifying the research question, locating relevant studies, selecting studies, charting the data, and collating, summarizing, and reporting the results.

2.1. Identifying the research question

We sought to answer related research questions: What are the educational interventions based on the internet to increase the physical activity of cancer survivors?

2.2. Identifying relevant studies

The literature study was done by publishing a published (resume) of research articles related to the research question. The search method used several electronic databases namely Google Scholar, Proquest, PubMed, and Scopus. Articles obtained from keywords: internet-based; supportive education; physical activity; cancer survivors Literature searches were completed on March 2, 2018. Relevant articles retrieved from the reference lists of relevant and selected articles were also included for screening.
2.3. Study selection

The inclusion criteria in this literature study were (1) study participants were individuals with a history of cancer who had completed active treatment (2) research article has peer review, full text and English language, (3) title and content relevant to research questions, (4) publication year from 2008 to 2018 and has a minimal research design quasi experiment. Exclusion criteria included articles that do not have the structure of a good article (consisting of abstract, introduction, methods, results, discussions, implications, and references), review articles and article content cannot answer research questions.

2.4. Charting the data and quality assessment

We performed the data extraction containing categorical domains, which could provide a clear and systematic description of the chosen articles. Microsoft Excel was used to summarize the relevant data. During data extraction, we analyzed the full texts of all 15 primary papers. Then we read the assigned articles and extracted the required data from the articles in order to answer the research questions. We collected three kinds of information from each paper. In the first step, standard information was gathered, like title of the article, place of research, sample size and research design.

The second and third steps included information directly related to answering the previously defined research questions. In the second step, the goal was to identify for type of cancer, physical activity measures and physical activity outcomes. The final step included gathering information about Interventions type, study duration and outcomes for included studies and the evaluation of the intervention.

3. Results (or Results and Discussion)

3.1. Study selection

We found 5375 studies through database searches. See figure 1 for the diagram of the study selection process. The search strategy initially identified 5375 records. Of these, 2112 articles were removed because duplicates, 2714 were excluded because of irrelevance to the topic. Strict inclusion criteria, as outlined above were applied to the full text of 93 articles. Of these, 15 were included in the final review. The majority of studies were published between 2012 and 2018, with one study published in 2011 and four in 2014. Sample sizes ranged between 10 and 352. All 15 studies assessed the impact of the internet base supportive education intervention on cancer survivor.

See table 1 for distribution of research sites and table 2 for research design. The majority of studies were located in USA and only one study took place in Asia. Fourteen studies were RCTs, and the remaining one was pre-post comparison studies.

3.2. Type of cancer

The majority of studies were breast cancer survivor that is 8 studies. Others are all types of cancers that have completed primary treatment, colorectal cancer and gynecological cancer.

We structured the results into three categories based on type of intervention, description of intervention, and outcomes. By organizing the paper in this way, we were able to systematically evaluate the evidence pertaining to each group, see how they interrelated, and were also able to evaluate for gaps in the literature. The outcomes that we focused on in this paper included various aspects of internet-based intervention to increase physical activity of cancer survivors.

3.3. Type of intervention

Based on the results of the review, the types of internet-based supportive education interventions to increase physical activity of cancer survivors are mobile application, online support group, email, social media posts, online workshop, My Tools, and help center. In addition there are also websites, social networking intervention programs, videosharing, LIFE Community, and Facebook-based interventions. All interventions can increase physical activity in cancer survivors.

3.4. Physical activity measures

All 15 included studies measured the impact of internet-based education on physical activity. All used self-reported PA as outcomes. Majority physical activity was assessed using Godin Leisure Time Exercise Questionnaire (GLTEQ) (8 studies) and the others use IPAQ, Seven-day Physical Activity Recall (PAR), Patient-Centered Assessment and Counseling for Exercise questionnaire. Short et al., (2017) also reported a resistance training score. McCarroll et al.,(2015) reported number of minutes of physical activity completed and the number of calories expended as logged via the participant using the mobile app used for their intervention. Puszkieicz et al., (2016) calculate a combined moderate-vigorous physical activity variable.

3.5. Physical activity outcomes

Most studies show improved results on intensity of physical activity. Participants in the internet-based intervention had significantly greater increases in minutes per week of vigorous exercise and stretching compared to controls (Bantum et al., 2014). Research by Pope, (2018) showed increases for average daily moderate to vigorous physical activity duration (2.6-min increase). In addition there was an increase in self-efficacy related to physical activity (3%). There was a significant increase in moderate-strong aerobic activity observed in all study groups. The online module intervention provides preliminary evidence that web-based interventions can be used to increase physical activity among breast cancer survivors. (Short et al., 2017). Multi-intervention approaches have shown more positive results than single interventions.
Figure 1. Diagram illustrating article selection strategy.

Records identified through database searching  
\( n = 5375 \)

Articles screened after removal of duplicates  
\( n = 3163 \)

Articles remaining for scrutiny of abstracts  
\( n = 449 \)

Full-text articles screened for eligibility

</tbody>
</table>

Based on table 4 above, the shortest duration of intervention time is 4 weeks and the longest intervention is 4 months. The average intervention time was 9.5 weeks. Most interventions used a duration of 12 weeks (53.3%).
<table>
<thead>
<tr>
<th>Author, Year</th>
<th>Outcomes</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pope et al, (2018)</td>
<td>In post intervention, increases were observed for average daily moderate to vigorous physical activity duration (2.6-min increase), with decreased average daily light physical activity and sedentary behavior seen as well. Improved physical activity-related self-efficacy (3% increase), social support (0.56 point increase), and enjoyment (0.15-point increase) were observed.</td>
</tr>
<tr>
<td>Forbes et al., (2015)</td>
<td>Results were more pronounced, though still non significant, among those not meeting guidelines at baseline where UCAN increased physical activity by 52 minutes compared to a decrease of 15 minutes in UC (adjusted between group difference=75, 95% CI -95 to 244; P=.38, d=0.27). There was a trend toward increased activity especially among inactive cancer survivors, although no significant differences were found.</td>
</tr>
<tr>
<td>Bantum et al, (2014)</td>
<td>Participants of Web-based interventions experienced significant insomnia reductions and greater increases in minutes per week of physical exercise and strong stretching compared with controls.</td>
</tr>
<tr>
<td>Rabin et al, (2011)</td>
<td>The findings revealed that 86% of the participants in the group’s website would recommend intervention to others and most (71%) were satisfied or very satisfied with it. Furthermore, 100% votes go to the website as very easy and 86% of the site's information is rated as very easy to understand. The logging feature, followed by feature goal setting, is most commonly accessed by participants. Participants also rated graphs and stage-matched useful manual features. The approximate effect size for differences between groups at 12 weeks was moderate for the results of physical activity and great for psychosocial outcomes. Interventions of internet based physical activity in young adult cancer survivors are feasible and acceptable and can be profitable.</td>
</tr>
<tr>
<td>Short et al., (2017)</td>
<td>This study provides preliminary evidence that interventions tailored to web-based computers can be used to increase physical activity among survivors of breast cancer. There was a significant increase in moderate-vigorous aerobic activity observed across all study groups. However, there were no significant effects of group observed on moderate-vigorous aerobic activity in either analysis (all ps &lt;0.05).</td>
</tr>
</tbody>
</table>
| Valle et al, (2014) | Over 12 weeks, both groups increased self-reported weekly minutes of moderate to vigorous physical activity (FITNET: 67 minutes/week, p=0.009 vs. SC: 46 minutes/week, p=0.045), with no significant difference between groups. Increases in light PA were 135 minutes/week greater in the FITNET group relative to the SC group (p=0.032), and the FITNET group reported significant weight loss over time (~2.1 kg, p=0.004; p=0.083 between groups). 
The Facebook based intervention approach shows the potential for increased physical activity in young adult cancer survivors. Social networking sites may be a viable way for young adult cancer survivors to receive health information and support to promote physical activity and healthy behaviors. |
| Valle & Tate, (2017) | Participants agreed that group discussion caused them to become physically active (p=0.040) and support group members (p=0.028). The post initiated by the participants gets more comments and likes significantly than moderator initiated posts. 
Response posts on Facebook significantly predicted light physical activity at 12 weeks, such that every increase of one response post in Facebook was associated with an increase of approximately 12 min/week in light-intensity PA (β = 11.77, t(85) = 1.996, p =0.049) |
| Hawkes et al., (2012) | From baseline to six weeks, improvements were observed for minutes moderate to vigorous physical activity (150.7 minutes). The research is acceptable and they will recommend it to others at risk of colorectal cancer. The positive behavioral changes achieved through this intervention approach have the potential to impact on the development of colorectal cancer and other cancers or chronic diseases. |
A significant improvement in pre- and post-intervention total WEL score was noted (99.38±41.8 versus 120.19±47.1, p=0.043). No significant differences were noted in FACT-G, macronutrient consumption, and physical activity patterns.

Median vigorous physical activity increased significantly from 0.0 to 360.0 MET minutes per week for the total group (P=.017), although this effect was not apparent in the subgroup analyses.

In both groups, social support from friends and self monitoring is positively associated with changes in the intensity of physical activity from moderate to strong. The FITNET group reported lower self efficacy for sticking to exercise (mean change=-0.38; 95% CI:-0.62 to -0.12; p=0.025) and social support from friends on social networking websites (mean change=-0.47; 95% CI: -1.45 to 0.65; p =0.039) relative to the self help comparison group over time. Changes in social support from friends on social networking websites partially mediated the intervention effects on moderate to vigorous physical activity (mean indirect effect = -22.4; 95% CI: -62.0 to -2.8) in the unexpected direction.

The findings suggest that women survivors of gynecological cancer feel participation in physical activity is important and provides benefits in terms of psychological well-being and improved physical function. Supports continuation of home-based program features.

Email based interventions based on Social Cognitive Theory can significantly affect the level of physical activity of breast cancer survivors. The analysis reveals a significant difference at 6 weeks (p=0.002) between the groups. At 12 weeks for total days of exercise, a significant difference was found (p<0.001).

Web-based programs that target changes in exercise and dietary behavior may be effective for breast cancer patients if the theory of the Trans Theoretical Model has been used to inform program strategy. Moderate intensity aerobic exercise for at least 150 min per week (p < 0.0001) and eating five servings of F&V per day (p = 0.001) significantly increased in the intervention group compared to controls.

Pre post comparison showed significant increases in strenuous physical activity, improvements in sleep quality, and reductions in mild physical activity. There were no significant changes in moderate physical activity or other psychosocial outcomes.
4. Discussion

The previous research among cancer survivors (Lee et al., 2014) and the meta-analysis by Davies et al (2012) found that computer-tailored physical activity programs had positive effects on physical activity. Previous reviews also indicate that Internet-delivered interventions have positive effects on physical activity levels (Lustria, Cortese, Noar, & Glueckauf, 2009). Internet-based education interventions can be given to cancer patients who are either undergoing treatment or who have finished treatment.

The majority of the studies used an online portal or website to deliver the intervention and only three studies used mobile applications. This study reported a significant effect of internet based supportive education to increase physical activity cancer survivors. Schmid et al. also reported that breast or colorectal cancer survivors who increased their physical activity by any amount between pre and post diagnosis showed a decreased total mortality risk (RR = 0.61, 95% CI 0.46–0.80) compared to cancer survivors who did not change their physical activity level or who were insufficiently active pre diagnosis (Schmid & Leitzmann, 2014). Different results are shown by McCarroll et al., (2015) where the increase in physical activity through mobile application intervention is not significant. Therefore, even small increases in moderate-vigorous physical activity post diagnosis are likely to be beneficial for cancer survivors.

The study showed that some cancer survivors are interested and willing to receive physical activity information through the internet; however, modifications to the website are necessary to optimize the effectiveness (Forbes et al., 2015)

Research by Puszkiewicz et al., (2016) using mobile application (GAINFitness) showed a significant increase in participants’ strenuous physical activity between T0 (median=40, IQR=105) and T1 (median=120, IQR=150), (z=-2.80, P=.002). Research by Pope, Lee, & Lee, (2018) using mobile app MapMyFitness and Facebook showed increases for average daily moderate to vigorous physical activity duration (2.6-min increase), with decreased average daily light physical activity and sedentary behavior seen as well [10]. Given the multitude of commercially available mobile device health applications and the large number of individuals who currently use mobile device health application and social media-based health education intervention may show promise in promoting cancer survivors’ physical activity.

As increased physical activity has been shown to reduce the symptoms of post-cancer treatment (eg, fatigue) and improve quality of life, innovative and practical interventions are needed to help survivors of cancer in regulating physical activity behaviors. Given the large number of commercially available mobile device health applications and the large number of individuals currently using mobile devices, combined mobile healthcare apps and social media-based health education interventions can be developed in promoting the physical activity of cancer survivors.

It’s possible that the intervention using a mobile app may be more effective than other types of Internet-based interventions due to widespread use and constant access to smartphones and the Internet. The latest Report Ofcom Communications Market conducted in the UK reported that 71% of adults in the UK have smartphones and 66% use their smartphones to access the Internet most often. Therefore, it would be interesting for future studies to use mobile apps as a way of delivering interventions and comparing the effectiveness of mobile app interventions as compared to other Internet-based interventions because it can encourage higher levels of engagement.

The review has shown that there is a positive relationship between participants’ compliance / involvement with interventions and positive physical health outcomes in various populations and behaviors, suggesting that efforts to increase effective engagement with internet-based education can improve the outcome of behavior change (Roberts et al., 2017).

Using an online portal or website to deliver interventions requires support of telecommunication infrastructure. The majority of studies take place in developed countries where their telecommunication infrastructure is advanced. While in developing countries where telecommunication infrastructure support is not enough to implement internet-based interventions will encounter many difficulties. As in Indonesia where there are still many areas that have no internet network. Including characteristics of cancer survivors’ rates are mostly in the middle and lower socioeconomic population and based on village / city area of cancer cases more in rural than in urban areas. Implementing internet-based interventions will encounter many difficulties.
5. Conclusions

The purpose of this scoping review was to identify internet-based supportive educational interventions to increase physical activity of cancer survivors. When we used these guidelines to investigate type of intervention and outcomes, we find that education through internet technology approaches can increase physical activity and health behaviors of cancer survivors. Suggested physical activity is based on The American College of Sports Medicine that cancer survivors must follow physical activity guidelines for at least 150 minutes with moderate intensity physical activity per week (Schmid & Leitzmann, 2014).

The findings of this scoping review showed that internet-based education can have a significant influence on changes in the increase in cancer survivors’ physical activity. In addition, it is possible that interventions using cellular applications are more effective than other types of use and constant access to smartphones and the internet. Therefore, this is a challenge for future applications to use cellular applications compared to other applications to increase cancer survivors’ physical activity.

All participants recommend interventions for future use. Physical activity interventions that combine commercially available mobile health applications and health interventions delivered on social media can promote specific physiological, psychosocial, and quality of life outcomes among cancer survivors.

Future research should consider the potential role of social media in addressing the unmet needs of survivors of cancer and in particular the implications for clinical and public health practice.

Funding: This research received no external funding.

Conflicts of Interest: The authors declare no conflict of interest.
